Interactive Preference-Aligned Lattice Pricing for Influencer Advertising with Additive Campaign Performance

Abstract

We formulate influencer advertising pricing as an interactive machine learning task where a campaign-agnostic, monotonic, and bounded lattice model is updated online using human price overrides and multidimensional performance outcomes. Under the practical assumption that performance vectors are additive within a campaign (when each influencer executes a single task), the learning objective simplifies to aligning channel-level price predictions with linear utility orderings of aggregate campaign performance. The resulting convex optimization problem admits efficient projected gradient updates and scales to streaming advertising deployments.

1 Hierarchical Data Structure and Notation

Let an advertising instance be denoted by $a_t = (c_t, \mathbf{x}_t)$, where:

- $c_t \in \mathcal{C}$ identifies the campaign (creative, audience targeting, brand, timing, etc.).
- $\mathbf{x}_t \in \mathcal{X} \subseteq \mathbb{R}_+^d$ is the vector of channel metrics (subscribers, engagement rate, historical views, etc.).

The pricing model operates at the channel level and outputs a predicted price $\hat{p}_t = f_\theta(\mathbf{x}_t) \in [0, p_{\max}]$. A domain expert may override this prediction, yielding a human-adjusted price p_t^{hum} . After deployment, a multidimensional performance vector $\mathbf{y}_t \in \mathbb{R}_+^k$ is observed (impressions, clicks, conversions, ROI, etc.).

1.1 Additivity Assumption (Accounting Perspective)

From an accounting and reporting standpoint, we assume that when each influencer executes at most one task within a campaign, performance aggregates linearly:

$$\mathbf{Y}_c = \sum_{a: c_a = c} \mathbf{y}_a, \quad P_c = \sum_{a: c_a = c} p_a, \quad (1)$$
